

UNIVERSITY OF ILLINOIS  
DIGITAL COMPUTER

LIBRARY ROUTINE F 7 - 312

**TITLE:** Integration of ordinary differential equations with automatic selection of elementary interval. (DOI or SADOI)

**TYPE:** Closed - one program parameter -- entered with link in Q. Upon being entered, the routine finds an optimum elementary interval, executes one step at that interval and returns control to the link address.

**ENTRIES:** Normal entry is at left of (F7) + 1 if (F7) is the location of the first word of this routine.

Special "initial entry": To start an integration off, put the initial values of the independent variable and the dependent variables into their data bank locations, put the appropriate program parameter into location 0 and enter at right of (F7) + 0. The initial sense of integration is always such as to increase the independent variable x.

Special "reversing entry": In order to effect a reversal of the sense of integration, enter at right of (F7) + 1 instead of at left. Subsequent normal entries will cause x to continue changing in the new sense until another reversing entry is made.

**NUMBER OF WORDS:** 210 plus data bank of  $10n + 2$  words.

**TEMPORARY STORAGE:** Locations 0, 1, 2; D + 7n to D + 10n - 1 inclusive.

**PRESET PARAMETERS:** Locations 3 and 4 must contain the following parameters during input of this routine:

| Location | Contents  | Significance   |
|----------|-----------|--|
| 3        | OOF 00 DF | D specifies the location of the data bank. See description of data bank.   |
| 4        | OOF 00 nF | n is the order of the system of differential equations, or the number of dependent variables obeying first order equations. Note that in order to revise D and/or n the F7 program must be read in over again. |

PROGRAM PARAMETER:

The program parameter must be supplied only at initial entry, when it must be put into location 0 before entering. It is a compound word of the structure:

$$(\ell_0 - m + 1) 2^{-7} + \omega 2^{-19} + (e + 1) 2^{-27} + \ell_0 2^{-39}$$

Here the integer  $\ell_0$  specifies the maximum size  $h_0^x = 2^{-\ell_0}$  of elementary interval to be permitted;  $m$  is an integer scaling parameter for the derivatives;  $\omega$  is the location of the first word of the auxiliary subroutine; and  $e$  is an integer specifying the accuracy asked for. The precise meaning of  $e$  is that the  $e^{\text{th}}$  binary digit in every  $y_i$  is to be correct after integrating from  $x_0$  to  $x_0 + 1$ .

The allowable ranges of the integer parameters are:

$$\begin{aligned} 0 &\leq m \leq 39 \\ 1 &\leq \ell_0 \leq 39 \text{ and } m \leq \ell_0 \\ \ell_0 - m &\leq e \leq \ell_0 - m + 39 \text{ and } e \leq 62 \end{aligned}$$

If the integer parameters violate these restrictions, then either the FF stop or a zero-shift stop will occur.

Note that  $\ell_0$ ,  $m$ ,  $\omega$  and  $e$  may be revised without reading the F7 program in over again, by making a new initial entry.

DURATION:

Normally about  $(2 \ln \text{ milliseconds} + 2T_\alpha)$  per elementary step, where  $T_\alpha$  is the time taken by the auxiliary subroutine to calculate derivatives. About 6n milliseconds additional is required when the interval must be revised. The initial entry, but only the initial entry, requires  $2^4$  or more times the above time.

FF STOP DURING OPERATION:

| Order with<br>Sexad. Address: | From<br>Location: | Significance:  |
|-------------------------------|-------------------|--|
| FF 04J                        | (F7)+0 left       | The tests indicate that an interval $< 2^{-39}$ would have to be used. Either faulty program (e.g., overflow) or too large an $e$ for single precision operation exists. |

FORM OF EQUATIONS:

In order to use this routine the system of ordinary differential equations to be integrated must be cast into the form

$$\frac{dy_i}{dx} = f_i(x, y_1, y_2, \dots, y_n); \quad i = 1, 2 \dots n$$

with  $x$  and  $y_i$  real numbers in machine range and  $f_i$  real numbers such that  $2^{-m}f_i$  are in machine range. Thus equations of higher than first order must be reformulated by introducing auxiliary dependent variables obeying first order equations; and the variables of the original scientific problem will in general have to be suitably scaled to make the problem conform to the above.

ELEMENTARY INTERVALS WHICH CAN OCCUR:

The computer's choice of elementary intervals is limited to positive and negative inverse powers of 2 (inverse  $2^0$  to inverse  $2^{39}$  power inclusive) because any other choices would much reduce the computing speed. Thus if a solution table is to be output with some constant interval, the independent variable  $x$  must be so scaled that the desired interval is represented by a power of 2 in the computer.

DATA BANK: The data bank is arranged as follows:

| Location | Contents                                   | Significance   |
|----------|--|--|
| D-2      | $x_0$                                      | initial value of independent variable                |
| D-1      | $x$  | current value of independent variable                |
| D        | $y_1$                                      | ) current rounded values of dependent variables      |
| D+1      | $y_2$                                      |  |
| -----    | -----                                      |  |
| D+n-1    | $y_n$                                      | )  |
| D+n      | $2^{-m}f_1$                                | ) current values of scaled derivatives               |
| -----    | -----                                      |  |
| D+2n-1   | $2^{-m}f_n$                                | )  |
| D+2n     | $a_1 \equiv 2^{-m}(h/2!) d^2 y_1 / dx^2$   | ) current scaled 2nd derivatives                     |
| -----    | -----                                      |  |
| D+3n-1   | $a_n \equiv 2^{-m}(h/2!) d^2 y_n / dx^2$   | )  |
| D+3n     | $b_1 \equiv 2^{-m}(h^2/3!) d^3 y_1 / dx^3$ | ) current scaled 3rd derivatives                     |
| -----    | -----                                      |  |
| D+4n-1   | $b_n \equiv 2^{-m}(h^2/3!) d^3 y_n / dx^3$ | )  |
| D+4n     | $c_1 \equiv 2^{-m}(h^3/4!) d^4 y_1 / dx^4$ | ) current scaled 4th derivatives                     |
| -----    | -----                                      |  |
| D+5n-1   | $c_n \equiv 2^{-m}(h^3/4!) d^4 y_n / dx^4$ | )  |
| D+5n     | $d_1 \equiv 2^{-m}(h^4/5!) d^5 y_1 / dx^5$ | ) current scaled 5th derivatives                     |
| -----    | -----                                      |  |
| D+6n-1   | $d_n \equiv 2^{-m}(h^4/5!) d^5 y_n / dx^5$ | )  |
| D+6n     |  | ) guard digits for $y_i$                             |
| -----    | -----                                      |  |
| D+7n-1   |  | )  |
| D+7n     |  | ) "predicted" values of $2^{-m}f_i$                  |

| D+10n-1  |  | )  |

The second and higher derivatives of  $y_i$  alluded to in this description are to be interpreted as higher derivatives of an approximating polynomial for  $y_i(x)$  and are developed automatically by the computer. The  $h$  which occurs in the description is the signed elementary increment to  $x$  which was used in the last elementary step done by the computer.

AUXILIARY SUBROUTINE:

The auxiliary subroutine reads the values of  $x$  and  $y_i$  from locations  $D-1$  to  $D+n-1$  and computes the scaled derivatives  $2^{-m}f_i$  and places them in locations  $D+n$  to  $D+2n-1$ . This subroutine must be supplied by the user since it depends on the particular system of differential equations he wants solved. It must be designed for standard subroutine entry, with link address in the  $Q$  register, and to be entered by transferring control to the left side of location  $\alpha$ . It must be capable of calculating the derivatives anywhere in the  $x$ -interval over which the equations are to be integrated, since the points at which the F7 routine will call for the derivatives are not known in advance. The accuracy of the auxiliary subroutine must be consistent with the accuracy demanded in the solution (a point sometimes overlooked), and this implies that  $2^{-m}f_i$  must be calculated correctly to  $e + m$  binary digits or 39 binary digits, whichever is the lesser number.

INFORMATION AVAILABLE UPON EXIT FROM THIS ROUTINE:

Most of the useful information is contained in the data bank, and for such the reader is referred to the above description of the data bank.

The "guard digit" locations  $D+n+i-1$  are initially (automatically) set to  $1/2$  so that the registers  $D+i-1$  will contain the rounded current values of the  $y_i$ . If the double precision value of  $y_i$  is desired, say to improve

the accuracy of the auxiliary subroutine arithmetic, it may thus be found from the formula

$$y_i = N(D+i-1) + 2^{-39} [N(D+6n+i-1) - 1/2]$$

The signed increment to x (signed elementary interval h) last used by the routine may be found in location (F7) + 209, which is the last word of F7. It is this value of h, including sign, which obtains in the data bank description.

The recommended procedure for finding  $y_i$  at an intermediate point, i.e., a point interior to the elementary interval, is to use the available approximating polynomial to interpolate. This is accomplished as follows:

- 1.) Integrate until the point of interest lies beyond  $x-h$  but not beyond  $x$ .
- 2.) Read out h and data bank locations D-1 to D+6n-1 inclusive.
- 3.) Let the point of interest be  $x-\theta h$ ;  $0 \leq \theta < 1$ . Then  $y_i(x-\theta h)$  is given with accuracy equivalent to the accuracy of  $y_i(x)$ , by the interpolation formula:

$$y_i(x-\theta h) = y_i(x) - 2^m \theta h [2^{-m} f_i - \theta a_i + \theta^2 b_i - \theta^3 c_i + \theta^4 d_i]$$

Roots and other similar functions of the solution are also best found by using the above interpolation procedure.

Other procedures for treating intermediate points, such as continually integrating with smaller and smaller interval in such a way as to converge on the point of interest, are awkward, time-consuming, and inaccurate compared to the above recommended procedure.

#### NOTES ON SCALING AND CHOICE OF $m$ , $l_0$ , $e$ :

The parameter  $m$  is provided so that the  $y_i$  and the  $f_i$  may be scaled independently for efficient use of the D+i-1 and D+n+i-1 registers. An obvious requirement is that the  $2^{-m} f_i$ , as well as the  $y_i$  and  $x$ , must all be within register capacity throughout the range of integration.

In general, if less than full register accuracy is required it is best to work near the less significant end of the registers, i.e., to scale the  $y_i$  so that they are small. The advantage of this is that  $m$  may be taken small, which in turn permits  $l_0$  to be taken small if desired for increased speed. Round-off errors will not propagate more than a few places into the  $y_i$  registers because of the guard digits kept.

$l_0$  should be chosen (a) large enough to guarantee availability of the solution of the printout or display intervals desired, and (b) so that  $2^{-l_0}$  is just larger than the largest elementary interval the computer will use, if the latter interval can be estimated. The penalty for specifying  $l_0$  too small is excessive automatic starting time, which is minor; whereas the penalty for  $l_0$  too large is excess time spent by the computer in developing a more accurate solution than asked for.

If some  $2^{-m}f_i$  has a relatively sharp temporary fluctuation in value in a narrow range of  $x$  (e.g., an approximation to a  $\delta$ -function) then one must guarantee, by taking  $l_0$  large enough or otherwise, that at least one point  $x = x_0 + (\text{integer}) 2^{-l_0}$  falls within the region of the fluctuation; otherwise, there is some risk of the computer missing the fluctuation entirely.

Discontinuities or "jumps" in  $2^{-m}f_i$ , if any, must not exceed 1/8 in magnitude so that the higher-derivative registers will not overflow during the process of integration past the discontinuity.

$e$  should be chosen after the scaling for the  $y_i$  has been chosen. If the maximum value of  $y_i$  is  $2^{-d}$  then there will be at least about  $(e-d)$  correct significant bits of the  $y_i$  developed after integrating from  $x_0$  to  $x_0 + 1$ . The maximum error tends generally to increase linearly with the range of integration, except that the number of correct

significant digits cannot be expected to exceed the initial number of significant digits. For "well-behaved" systems of equations, namely ones such that

$$2^{-m} \left| \frac{df_i}{dx} \right| \approx 1$$

the error is generally less than  $2^{-e}$ , typically  $2^{-e-4}$ . For very ill-behaved equations, such that

$$2^{-m} \left| \frac{df_i}{dx} \right| \approx 2^{36}$$

the error will in general be larger, typically  $2^{-e+1}$ .

A more precise estimate of the error in a particular result may be got by using two different e's in turn and observing which digits in  $y_i$  change. e should be changed by at least 3 or 4 units in this process.

The relationship between the value of e specified and the interval automatically chosen by the computer is as follows. The interval h chosen is the largest interval satisfying all of the three conditions:

$$|h| \leq 2^{-e} \ell_0; \quad \left| h \frac{\partial f_i}{\partial y_j} \right| \leq 0.38; \quad h^6 |d^6 y_i / dx^6| \leq 3 \cdot 2^{-e}$$

In the last of these conditions the 6th derivative is to be interpreted as the 6th derivative of an approximating polynomial developed by the computer for  $y_i(x)$ . The second of the above conditions guarantees the stability of the numerical procedure and minimizes inherited errors in cases where such errors are strongly magnified. The third condition bounds the truncation error in such a way as to supply the final accuracy specified via the accuracy parameter e.

TO FREEZE THE INTERVAL:

The following modifications will transform the F7 routine into a fixed-interval routine operating with elementary interval  $h = \pm h_0 = \pm 2^{-l} h_0$ . The accuracy parameter  $e$  and all interval controlling tests will be ignored.

| At:       | Overwrite:      | With:                              |
|-----------|-----------------|------------------------------------|
| (F7) + 48 | 32 55L F5 139L  | 36 ((F7) + 74) F F5 ((F7) + 139) F |
| (F7) + 81 | 40 110L 40 207L | 50 F 40 ((F7) + 207) F             |

Warning: The accuracy and stability of the procedure may suffer in such a fixed-interval application if the condition

$$\left| h_0 \frac{\partial f_i}{\partial y_j} \right| \leq .38$$

is not satisfied.

DESCRIPTION OF ROUTINE:

A detailed description of the method used in this routine may be found in University of Illinois Coordinated Science Laboratory Report R-127, "On Numerical Integration of Ordinary Differential Equations," May, 1961, by Arnold Nordsieck; also to be published in "Mathematics of Computation," Journal of the Division of Mathematics, National Academy of Sciences - National Research Council, Washington, D. C., about October, 1961.

The method works with polynomials of 5th degree approximating to each of the  $y_i$ , and these polynomials are specified by their 0th to 5th derivatives in order to facilitate changes of interval. (Actually the derivatives beyond the first are multiplied by  $2^{-m}$  and by a power of the current elementary interval  $h$  and divided by a factorial, as indicated in the data bank description, in order to keep them in machine range and to facilitate the arithmetic).

Equations with discontinuous derivatives are integrable by this method with accuracy comparable with the accuracy for the case of continuous derivatives provided only that

the jumps in the derivatives are finite and are scaled according to the restriction stated on page 7.

The elementary step from  $x$  to  $(x + h)$  consists of applying the working equations:

$$\begin{aligned}
 y_i(x+h) &= y_i(x) + 2^m h (2^{-m} f_i(x) + a_i(x) + b_i(x) + c_i(x) + d_i(x) + \frac{95}{288} [2^{-m} f_i(x+h) - 2^{-m} f_i^p]) \\
 2^{-m} f_i^p &\equiv 2^{-m} f_i(x) + 2a_i(x) + 3b_i(x) + 4c_i(x) + 5d_i(x) \\
 a_i(x+h) &= a_i(x) + 3b_i(x) + 6c_i(x) + 10d_i(x) + \frac{25}{24} [2^{-m} f_i(x+h) - 2^{-m} f_i^p] \\
 b_i(x+h) &= b_i(x) + 4c_i(x) + 10d_i(x) + \frac{35}{72} [ \quad \quad \quad ] \\
 c_i(x+h) &= c_i(x) + 5d_i(x) + \frac{5}{48} [ \quad \quad \quad ] \\
 d_i(x+h) &= d_i(x) + \frac{1}{120} [ \quad \quad \quad ]
 \end{aligned}$$

Here the quantities evaluated at  $x$  are known from the previous elementary step (except in the very first step, in which case the "initial entry" must be used and an automatic starting procedure is invoked; see below); and the quantities at  $(x + h)$  are to be found. The coefficients  $95/288$ ,  $25/24$ ,  $35/72$ ,  $5/48$ ,  $1/120$  are specially chosen to maximize the stability of the method, to optimize the process of integration across finite discontinuities of the derivatives, and to make the truncation error  $O(h^7)$  rather than  $O(h^6)$  as it would be for arbitrary coefficients. The truncation error in  $y_i$  per elementary step is

$$E_t = + \frac{h^7}{70} \frac{d^7 y_i}{dx^7} + O(h^8)$$

provided the seventh derivative exists.

The solution of the working equations proceeds in three stages. Stage 1 consists of "predicting" all six quantities  $y_i \dots d_i$  at  $x + h$ , i.e., applying the working equations

without the [ ] terms, using as tentative value of h the value which was accepted in the last previous step, or twice that value if the conditions for doubling h were fulfilled. Stage 2 consists of solving the complete first working equation, which is an implicit equation since the  $f_i(x+h)$  depend on the  $y_i(x+h)$  in virtue of the differential equations. The equation is solved iteratively by inserting the "predicted"  $y_i$  on the right, appealing to the auxiliary subroutine for  $f_i(x+h)$ , thus producing first improved  $y_i(x+h)$ , appealing again to the auxiliary subroutine and thus finally getting second improved  $y_i(x+h)$ . The iterative procedure is always terminated after just these two iterations, the second improved  $y_i(x+h)$  and  $f_i(x+h)$  being accepted as adequate approximations.

At completion of stage 2 two tests are made to determine whether h is sufficiently small. One test determines whether or not the iterative solution of the implicit equation was sufficiently convergent, and this comes to whether or not

$$\frac{95}{288} \left| h \frac{\partial f_i}{\partial y_j} \right| \leq 1/8$$

because the left side of this inequality is the convergence factor. The second test determines whether the truncation error is small enough to be consistent with the accuracy parameter e, and this comes to whether

$$|f_i(x+h) - f_i^p| \leq (3.03) 2^{-e}/|h|$$

If either of these tests is violated we discard the computations of stages 1 and 2, halve h and enter upon stage 1 again. If both tests are satisfied we ascertain whether they are "oversatisfied," i.e., whether a doubled h would likely satisfy them, and if so note this fact for future reference; then proceed to stage 3, which consists of "correcting"  $a_i, b_i, c_i, d_i$  by adding the [ ] terms.

The above discussion indicates the conditions for automatic reduction of interval. If the tests are not satisfied even after the interval has been reduced to  $2^{-39}$  the FF stop is invoked. The conditions for increasing the interval, on the other hand, are as follows: If before entering stage 1 we have  $|h| < 2^{-l_0}$  and both tests were previously "oversatisfied" and the digits of  $(x-x_0)$  are such that doubling  $h$  will not cause the next point  $x = x_0 + (\text{integer}) 2^{-l_0}$  to be missed, then  $h$  is doubled before stage 1 is entered; but after a reversal of sense of integration  $h$  may not be doubled until 4 elementary steps have elapsed. The last condition is necessary to discourage occasional erratic interval behavior after reversal.

Automatic starting is a special procedure automatically invoked before the first step away from the initial value  $x_0$ , when neither the correct  $h$  nor the quantities  $a_i \dots d_i$  are known. This feature relieves the user of the task of supplying special starting information and requires him to supply only the logically essential initial values of the  $y_i$ .

In the automatic starting mode the computer clears the  $a_i \dots d_i$  locations and then repeatedly integrates four steps forward and four steps back to  $x_0$ . Because of the high degree of stability of the method the quantities  $a_i \dots d_i$  converge rapidly to the correct values in this process, which is thus a successive approximation method of a special sort for fitting a 5th degree polynomial to  $y_i(x)$  near  $x_0$ . During starting the interval is also decreased as necessary, so that when the process is complete the correct  $h$  as well as the correct  $a_i \dots d_i$  have been established. Thereafter one meaningful forward step is taken and control is returned to the link address. From the point of view of the user the first step is just like any other step except that a) he must supply

the initial conditions and the program parameter and enter by the "initial entry," and b) it takes 24 or more times as long as other steps.

Complete details of the starting process and of the whole method in general are given in the paper "On Numerical Integration of Ordinary Differential Equations" referred to above.
